## ABSTRACT

The OH-stretching fundamental, and the first, second, and third OH overtone vibrations have been examined using pure, and GeO<sub>2</sub>-doped graded index, fused silica optical fibers having OH contents from <1 ppm to >10<sup>2</sup> ppm. The previously reported component substructure of the fundamental OH-stretching contour was found to be repeated in the overtones, along with a set of combinations involving fundamental vibrations of fused silica. Several new vibrations were uncovered and assigned. Examinations of deuterated OH samples helped to verify the assignments. The spectral proceduring produced by GeO<sub>2</sub> was interpreted in terms of a wider range of environments seen by he OH oscillators, compared to pure fused silica.

#### 1. Introduction

The overtone vibrations of the OH group in fused silica, particularly the first overtone, are of considerable practical importance because they give rise to transmission losses in long optical fibers. (1) The OH-stretching overtones are also of interest from a fundamental point of view because they provide evidence relating to bonding and structure in fused silica (2) as well as in other glasses. (3,4,5)

When water is incorporated into fused silica, silanol groups, Si-OH, are formed, (6) as opposed to the discrete H<sub>2</sub>O molecules found in crystalline quartz. (7) Further, the vibrational frequencies of the OH groups in fused silica are sensitive to the surrounding environment because the OH vibrations are decoupled dynamically from the Si versus OH vibrations. The fundamental OH-stretching vibrations occur within the 3000-4000 cm<sup>-1</sup> region, whereas the Si versus OH stretching occurs near 970 cm<sup>-1</sup>. (6) This environmental sensitivity leads to structured fundamental and overtone OH-stretching contours in both the infrared and Raman spectra, the analysis of which provides an understanding of the structure and properties of the wet glass.

Examination of the shapes of the fundamental Raman and infrared OH-stretching contours from pure fused silica indicates the presence of substructure. The maxim in Raman and infrared intensities occur at 3690 cm<sup>-1</sup> and 3665 cm<sup>-1</sup>, (2,8) respectively, and each spectrum shows a shoulder near 3610 cm<sup>-1</sup>, (2,8) there is also a maximum in the depolarization ratio near 3620 cm<sup>-1</sup>, (8) These observations constitute definite physical evidence for three OH-stretching components near 3690 cm<sup>-1</sup>, 3665 cm<sup>-1</sup>, and 3610 cm<sup>-1</sup>. Further, decomposition of the Raman and infrared OH-stretching contours into Gaussian components indicates a fourth broad, weak component near 3510 cm<sup>-1</sup>, (2) The component substructure should thus also be evident in the overtones, although complications due to anharmonicity, or to combinations, etc., are to be expected. (The detailed nature of the interactions leading to the four OH-stretching components has been described previously, (2) and will not be

#### considered here.)

In this work we have examined the first, second, and third OH-stretching overtones in long lengths of fused silica optical fibers, and re-examined the fundamental region for thick silica samples, both deuterated and undeuterated. We also have obtained the Raman spectrum of the first OH-stretching overtone, which is extremely weak.

The picture that emerges is one in which the fundamental contour consists of three or four OH-stretching components, plus several combination to see. These features are repeated in the substructure of the first three overtones, and can be identified in slightly modified form in the OH overtone substructure of  $GeO_2$ -doped silice. Several weak features of the absorption spectra, some previously unreported, are explained. Also, we observed a resolved absorption maximum in a deuterated sample which may trise from a combination mode which is unresolved in the undeuterated spectrum. The details of the present fundamental and overtone observations and assignments follow.

## 2. Experimental

.

Fundamental infrared absorbance spectra in the range of 600 to 4950 cm<sup>-1</sup> were obtained from samples of Suprasil-2, Spectrasil, and Amerail FO-8, and also from samples of the same materials in which the OH was partially deuterated by OH COD exchange. (9) The OH content of the undeuterated samples ranged from about 10<sup>2</sup> to 10<sup>3</sup> ppm. The absorbance spectra were obtained with a Nicolet 7000 Fourier transform infrared (FTIR) instrument. Each absorbance spectrum is the Fourier transform of an average of 128 interferograms. FTIR difference spectra were also obtained from linear combinations of deuterated and undeuterated absorbance spectra.

Deuterated samples of Suprasil-2, Spectrasil, and TO-8 in the form of rods ~1 cm in diameter were obtained by OH=OD exchange. The rods were bested for 5 days at 1000°C in a D<sub>2</sub> atmosphere to produce the isotopic exchange. However, because the deuteration was not complete, a small fraction of the original OH remained. The deuterated rods were then cut

into appropriate lengths and the ends were optically polished.

In order to observe the OH-stretching overtone spectra, it was necessary to use very long sample lengths. This was accomplished by the use of optical fibers. Appropriate lengths were used depending on the OH content of the silica, and the overtone under study. (The maximum absorbances per cm of the OH-stretching fundamental and overtones are: fundamental,  $10^{-2}$ /ppm OH; first overtone,  $5\times10^{-5}$ /ppm OH, second overtone,  $10^{-6}$ /ppm OH; and, third overtone,  $10^{-7}$ /ppm OH.)<sup>(9)</sup> Fibers of Spectrasil (>10<sup>3</sup> ppm OH), Suprasil (>10<sup>3</sup> ppm OH), and Amersil TO-8 (>10<sup>2</sup> ppm OH) were made by drawing silica rods to a diameter of 125  $\mu$ m in an electric furnace. A protective coating of Nylon was added immediately after drawing. The GeO<sub>2</sub>-doped silica fibers were graded-index multimode, or step-index single-mode core, silica-clad fibers, with plastic outer coating of the type commonly used in fiber optics research. The light-guiding core of the graded-index fiber has a GeO<sub>2</sub> concentration varying from about 14 percent at the center, to zero at the core-cladding boundary (parabolic profile). Thus its absorption spectrum represents a weighted average of those from pure silica to 14 percent GeO<sub>2</sub>. The core of the single-mode fiber is uniformly doped with about 5 percent GeO<sub>2</sub>.

When light propagates in a low-loss optical fiber, attenuation in the spectral regions of the OH-stretching overtones results mainly from the overtone absorption--the attenuation from Rayleigh scattering is relatively small. When light enters the core of an optical fiber, the decrement in the light power spectrum  $I_L(\lambda)$  is given by

$$dI_{L}(\lambda) = -\left[\alpha_{g}(\lambda) + \alpha_{g}(\lambda)\right]I_{L}(\lambda)dL , \qquad (1)$$

where  $\alpha_{\bf g}(\lambda)$  is the absorption loss coefficient,  $\alpha_{\bf g}(\lambda)$  is the scattering loss coefficient, and  $\lambda$  is the wavelength. Then

$$I_{L_2}(\lambda) = I_{L_1}(\lambda) e^{-[ag(\lambda) + ag(\lambda)](L_2 - L_1)}$$
(2)

and

The second second

$$\alpha_{g}(\lambda) + \alpha_{b}(\lambda) = \frac{1}{L_{2} - L_{1}} \ln \frac{I_{L_{1}}(\lambda)}{I_{L_{2}}(\lambda)} , \qquad (3)$$

where  $L_1$  and  $L_2$  are fiver lengths for which the emergent light is measured (for a fixed light input). Because  $\alpha_g(\lambda)$  and  $\alpha_g(\lambda)$  are additive, the absorbance contour can be taken as the portion of the attenuation spectrum above the background scattering curve. In the present work a tungsten-halogen lamp was employed as a light source. Spectra were obtained with a Jarrell-Ash 0.25 m mor ochromator; we determined that the resulting spectral shapes were not limited by the low instrumental resolution. Because the absorbance measurement performed here is a ratio measurement, it is independent of factors related to the spectral sensitivity of the measurement system.

Raman spectra of the first OH-stretching overtone region were also obtained using 20 to 115 m of pure fused silica fiber having OH contents ranging from about 500-1300 ppm. Interference-filtered argon ion laser radiation at 488.0 nm was used for excitation, with an Instruments S.A. HG2S holographic grating double monochromator having enhanced red sensitivity. The overtone Raman spectra were extremely weak, however, and yielded data of limited value.

Infrared fundamental and overtone contours were decomposed into Gaussian components using a DuPont 310 analog computer.

## 3. Experimental Results

## A. Infrared Fundamental OH- and OD-Stretching Region

FTIR absorbance spectra corresponding to the fundamental OH-stretching region (3100-4900 cm<sup>-1</sup>) from Spectrasil and Suprasil-2 samples, both containing ~10<sup>3</sup> ppm OH are shown in Fig. 1. The absorbance scale was expanded to show the presence of weak, newly observed components. Components previously reported at 3690, 3665, 3605-3620, and 3510 cm<sup>-1</sup>(2) occur within the saturated peak. Fig. 1 shows a pronounced shoulder at 3850 cm<sup>-1</sup> and a weak maximum at 4520 cm<sup>-1</sup>. The weak foot at 4100 cm<sup>-1</sup> and the shoulder near 4450 cm<sup>-1</sup> constitute newly observed features.

The 3100-4900 cm<sup>-1</sup> region of the spectrum is also shown in Fig. 2 for a deuterated sample of Spectrasil. The appearance of a resolved maximum at 3340 cm<sup>-1</sup> is noteworthy.

To show the OD-stretching region of the deuterated sample without interference from silica overtones, an FTIR difference spectrum,  $A_{\rm OD} - k$   $A_{\rm OH}$  (here k=3.981) computed from a linear combination of deuterated,  $A_{\rm OD}$ , and undeuterated,  $A_{\rm OH}$ , absorbance spectra, was required, Fig. 3. The OD-stretching shoulder shown in the figure near 2850 cm<sup>-1</sup> is the analog of the OH-stretching shoulder at 3850 cm<sup>-1</sup>.

Infrared difference peaks at 775  $\pm$  10 and 950  $\pm$  10 cm<sup>-1</sup> were obtained from Suprasil-2 and deuterated TO-8, Fig. 4. The peak at 950  $\pm$  10 cm<sup>-1</sup> was observed and assigned in previous Raman studies (5,6,11) to Si versus OH stretching. The peak at 775  $\pm$  10 cm<sup>-1</sup> is new, and is assigned to the torsional oscillation  $\gamma$ (OH) of protons in bent Si-O-H units.

The major components of the fundamental OD-stretching contour were also obtained from infrared difference spectra,  $A_{OD} = k A_{OH}$ . Computer analysis revealed four Gaussian components near 2720  $\pm$  10, 2700  $\pm$  10, 2670  $\pm$  10, and 2595  $\pm$  20 cm<sup>-1</sup>.

All results of this section are tabulated in Table I.

## B. First, Second, and Third Overtone OH-Stretching Contours of Pure Silica

Infrared absorbance spectra corresponding to the first, second, and third OHstretching overtones have been obtained using optical fibers. These spectra are shown in
Figs. 5, 6, and 7. Each continuous was analyzed into Gaussian components as shown in
the figures. It is evident that the decomposition could be accomplished with four components,
and that the set of components is very similar for each overtone, both in relative amplitude and
in relative width.

The Gaussian component peak frequencies  $\vec{r}$  from Figs. 5, 6, and 7 are plotted in terms of  $\vec{r}/v$  versus v in Fig. 8. (The vibrational quantum number of the upper state is here designated by v.) When the apparently related components of the various overtones are connected by smooth lines, correlation with the fundamental is obvious and unequivocal. (Anharmonicity requires that the curves decrease monotonically.) The curved lines shown in Fig. 8 represent least squires fits to an equation in which  $\vec{r}/v$  is quadratic in v. The curves labeled 1, 2, and 3 have a milar shapes (downward concavity), whereas the curve labeled A, has a markedly different shape (upward concavity). An explanation for the opposite curvature of curve A involving a combination vibration is given in Section 4(B).

Components corresponding to the fundamental region and to the Gaussian components of Figs. 5, 6, and 7 are bracketed in Table I, and grouped according to the correlations of Fig. 8 in Table II.

## C. Raman Spectrum of the First OH-Stretching Overtone

Raman spectra of the OH-stretching overtone were obtained using pure fused silica optical fibers with OH contents between 500 and 1300 ppm. The Raman signal obtained was  $10^4$  times weaker than the fundamental signal, in part because of decreasing system sensitivity at the Raman wavelength. Broad weak asymmetric contours on a strongly sloping background were observed which perked near 7225 ± 50 cm<sup>-1</sup>. The Raman overtone contour exhibited rapid high-frequency fall off and a low-frequency tail, i.e., its appearance was similar to that of

the fundamental. The agreement between the overtone Raman peak position at  $7225 \pm 50 \text{ cm}^{-1}$  and the first infrared overtone at  $7260 \text{ cm}^{-1}$  is satisfactory in view of the weakness of the Raman spectra.

# D. First and Second OH-Stretching Overtone Absorptions from GeO2-doped Optical Fibers

We also obtained OH-stretching overtone spectra of GeO<sub>2</sub>-doped optical fibers. Both the graded-index multimode fibers, and the step-index single mode fibers, described earlier, were employed. For the graded-index fiber, a length of 500 m was needed to on ain the first overtone spectrum, and a length of 900 m was required for the second overtone. The third overtone could not be observed clearly because of the low OH content (<1 pmm). Also the Rayleigh scattering loss is predominant over the OH absorption loss at the shorter wavelengths resulting in a very steep background level above which the absorption profile had to be measured. These spectra are shown in Figs. 9 and 10. As in the case of the spectra from pure silica fibers, we could resolve each OH-stretching contour into four Gaussian components, two broad and two narrow, with similar relative heights and widths for the three controles. However, when Figs. 5 and 6 are compared to Figs. 9 and 10, it is apparent that a major difference results from the GeO<sub>2</sub> doping, namely, that the amplitude and breadth of component 2 increased for the doped sample. Instead of being slightly weaker and slightly broader than component 1, as for pure silica, component 2 becomes much more intense and much broader, resulting in a significant broadening of the entire OH-stretching contour.

Finally, an example of intermediate  $GeO_2$  doping is shown in Fig. 11. Here the spectrum corresponds to the first OH-stretching overtone from a single mode fiber, with a  $GeO_2$  concentration of 4-5 percent. This contour was also decomposed into four Gaussian components, with component 2 displaying a relative width (but not a relative amplitude) intermediate between that from the pure silica and the graded-index fibers.

The relative peak heights and half-widths of the Gaussian components from the pure silica and GeO2-doped silica are given for the fundamental and overtone vibrations in

Table II.

## 4. Discussion and Assignments

## A. The Fundamental OH Spectrum

Components observed in the fundamental OH-stretching spectrum are listed in Table I. The components at 3510, 3605-3620, 3665, and 3690 cm<sup>-1</sup> have been previously identified with OH-stretching vibrations involving different silica environments. (2) Their analogs in the OD spectrum are also listed in Table I. The set of neighboring OH components at 3850, 4100, and 4450-4520 cm<sup>-1</sup>, however, cannot refer to fundamental OH-stretching vibrations, because the fundamental OH-stretching frequency from H<sub>2</sub>O extrapolated to zero density at 400 C is 3750 cm<sup>-1</sup>. (12) Thus, it appears that these components are combinations with silica vibrations.

For fused silica, strong infrared absorption peaks occur near 1110, 810, and 450 ± 10 cm<sup>-1</sup> (this work). Further, Raman features within the one-phonon region occur near 60 (peak), 115 (shoulder), 280 (shoulder), 350-375 (shoulder), 432 (peak), 490 (peak), 605 (peak), 800 (peak), 825 (shoulder), and 1060 (peak) cm<sup>-1</sup>. (6,13) The 1060-1110 cm<sup>-1</sup> vibration arises from Si-O stretching, (6) the 800-810 cm<sup>-1</sup> vibration from Si-O-Si bending, (14) and the 432-450 cm<sup>-1</sup> vibration may arise from an oxygen vibration along the Si-O-Si bridging bisector in which no Si motion is involved. (15) The 490 and 605 cm<sup>-1</sup> peaks arise from silica network defects. (6,13) The remaining frequencies are poorly understood.

Although a complete vibrational picture is lacking, it is expedient in this work to employ a gressly over-simplified nomenclature. This nomenclature happens to employ four vibrations which are convenient for our further analysis, and which refer to the  $T_d$  symmetry that the SiD tetrahedra would have if they were not linked on all corners to neighboring tetrahedra, namely,  $\vec{r}_3 = 1060(1110) \text{cm}^{-1}$ ,  $\vec{r}_1 = 800(810) \text{cm}^{-1}$ ,  $\vec{r}_4 = 432(450) \text{cm}^{-1}$ , and  $\vec{r}_2 \approx 280 \text{ cm}^{-1}$ . (Recent Gaussian component analysis of Raman contours has indicated that  $\vec{r}_2$  may be closer to 240 cm<sup>-1</sup> or below. (17)) Further, to distinguish silica from OH

vibrations, we append the suffixes SiO<sub>2</sub> and OH to the vibrational designations.

Using the nomenclature described, we assign the four features between 3350 and 4520 cm<sup>-1</sup> as follows:  $3850 \text{ cm}^{-1}$ ,  $\tilde{r}_3(\text{OH}) + \tilde{r}_2(\text{SiO}_2)$ ;  $4100 \text{ cm}^{-1}$ ,  $\tilde{r}_1(\text{OH}) + \tilde{r}_4(\text{SiO}_2)$ ;  $4450 \text{ cm}^{-1}$ ,  $\tilde{r}_1(\text{OH}) + \tilde{r}_1(\text{SiO}_2)$ ; and  $4520 \text{ cm}^{-1}$ , (possibly)  $\tilde{r}_4(\text{OH}) + \tilde{r}_3(\text{SiO}_2)$ . Evidence for these assignments is presented in Section B.

## B. Overtone Spectra

From the assignments of the fundamental OH vibrational spectrum given in Section A, it is possible to treat the overtone spectra in a satisfactory manner, consistent with anharmonicity and infrared overtone activity. In Fig. 8, Section 3(B), we identified the  $\overline{\nu}/\nu$  values for  $\nu = 1$  on curves 1, 2, and 3 as OH-stretching fundamental components. In Section 4(A) we assigned the A curve of Fig. 8 to a combination tone. However, treatment of the 3850 cm<sup>-1</sup> combination by the method of Fig. 8 yields a curvature different from that of components 1, 2, and 3. The combination labeled A in Fig. 8 refers to the case where

$$\frac{\overline{y}}{y} = \frac{\overline{y}(OH)}{y} + \frac{\overline{y}(SiO_2)}{y} . \tag{4}$$

Here,  $\overline{r}(OH)$  refers both to fundamental and overtones, whereas  $\overline{r}(SiO_2)$  refers only to the fundamental, and v refers only to the OH vibrational levels. Because  $\overline{r}(SiO_2)$  is constant,  $\overline{r}(SiO_2)/v$  decreases with increasing v, and thus the curvature of component A, Fig. 8, must be different from the curvatures of components 1, 2, and 3. (The treatment of combinations according to eqn. (4) reduces the number of phonons in the combination to a minimum for the various OH overtones.)

Component A and other combination tones are better treated by the method of Fig. 12. In Fig. 12 the quantity  $[\vec{r} - \vec{r}(SiO_2)]/v$  is plotted versus v. Here  $\vec{r}$  refers to combination vibrations. The case where  $\vec{r}(SiO_2) = 0$  yields curves 1, 2, and 3, taken from Fig. 8. Definitions of other quantities, eqn. (4), still apply.

Consider next the three frequencies of Table I at 4450, 8065, and 11470 cm<sup>-1</sup>, which are assigned as  $\bar{\nu}_1(OH) + \bar{\nu}_1(SiO_2)$ ,  $2\bar{\nu}_1(OH) + \bar{\nu}_1(SiO_2)$ , and  $3\bar{\nu}_1(OH) + \bar{\nu}_1(SiO_2)$ , respectively. From Fig. 12, it is evident that these combinations fit reasonably well to curve 1, for the case where  $\bar{\nu}_1(SiO_2) = 800$  cm<sup>-1</sup>.

Now consider the four frequencies of Table I at 3850, 7380, 10750, and 13950 cm<sup>-1</sup>. Again from Fig. 12, it is evident that these four frequencies fit curve 3 reasonably well for  $\vec{r}_2(\text{SiO}_2) = 280 \text{ cm}^{-1}$ , or even better for the Gaussian component value of 240 cm<sup>-1</sup>. The assignments and as follows: 3850 cm<sup>-1</sup>,  $\vec{r}_3(\text{OH}) + \vec{r}_2(\text{SiO}_2)$ ; 7380 cm<sup>-1</sup>,  $2\vec{r}_3(\text{OH}) + \vec{r}_2(\text{SiO}_2)$ ; 10750 cm<sup>-1</sup>,  $3\vec{r}_3(\text{OH}) + \vec{r}_2(\text{SiO}_2)$ ; and, 13950 cm<sup>-1</sup>,  $4\vec{r}_3(\text{OH}) + \vec{r}_2(\text{SiO}_2)$ .

Finally, the frequencies of 4100, 4520, and 7920 cm<sup>-1</sup> are assigned in Table I to the combinations,  $\bar{r}_1(OH) + \bar{r}_4(SiO_2)$ ,  $\bar{r}_4(OH) + \bar{r}_3(SiO_2)$ , and  $2\bar{r}_3(OH) + \bar{r}_1(SiO_2)$ , respectively. Again from Fig. 12, it is evident that reasonable fits are obtained for  $\bar{r}_4$ ,  $\bar{r}_3$ , and  $\bar{r}_1(SiO_2)$  values of 432, 1060, and 800 cm<sup>-1</sup>, respectively.

One problem would appear to arise from the above combination assignments involving the 280 and 800 cm<sup>-1</sup> vibrations, in that neither of these vibrations corresponds to the highest infrared intensity. However, computer analysis of infrared absorbance spectra, indicates that the integrated absorbance of the 280 cm<sup>-1</sup> Gaussian component may be roughly 30-50 percent of the integrated absorbance at 450 cm<sup>-1</sup>. Further, Gaussian computer analysis of Raman contours from fused silica indicates that the 280 cm<sup>-1</sup> component (closer to 240 cm<sup>-1</sup>) is one of the strongest components in the spectrum. The 800 cm<sup>-1</sup> feature, of course, is prominent in both the Raman and infrared spectra. Thus, the intensity problem, if it exists, does not seem compelling compared to the treatment of Fig. 12, which appears to require vibrations at 280 and 800 cm<sup>-1</sup>.

# C. Comparations Involving Oversome Components-from GeO2-doped Fused Silica

Comparisons of Gaussian OH-stretching overtone components between Figs. 5 and 6 and Figs. 9 and 10 indicate that the most conspicuous difference involves component 2. The

amplitude and width of this component increases with GeO<sub>2</sub> doping compared to the other components, especially component 1.

In wet fused silica, component 1 is thought to refer to OH oscillators that are essentially gas-like, whereas component 2 is thought to refer to strongly bent O-H--O units, hence nonhydrogen-bonded. The intensification of component 2, relative to component 1 in GeO<sub>2</sub>-doped fused silica, suggests that the presence of GeO<sub>2</sub> removes those environments, e.g., gas-like or dangling OH groups whose presence gives rise to the high-frequency OH component, 1. Further, the broadening of component 2 indicates a nore varied environment for the doped glass, compared to pure fused silica.

In regard to a more varied environment in GeO<sub>2</sub>-doped fused silica, it should be stated that Raman spectra from fused silica doped with 13 percent GeO<sub>2</sub> show features not present in either pure fused silica or pure GeO<sub>2</sub> glass, namely, weak components at 675 and 1000 cm<sup>-1</sup>. These new features are probably associated with Ge-O-Si bridges. Such bridges would lead to a more varied environment in the mixed glass, and Je-O-Si-OH as well as Si-O-Ge-OH linkages would be expected to occur.

Finally, the fundamental OH-stretching Raman peak from wet GeO<sub>2</sub> glass occurs near 3590-3600 cm<sup>-1</sup> and a prominent low-frequency shoulder is also present. These Raman OH-stretching features from wet GeO<sub>2</sub> glass would correspond to components 3 and 4 of Table II. However, it is component 2 that shows the strong relative intensification and broadening with GeO<sub>2</sub> addition. Thus, from this observation and from examinations of frequency shifts of various components, it is evident that Figs. 9 and 10 are not simple superpositions of spectra from OH in pure silica or pure GeO<sub>2</sub> glass.

## 5. Summary

The infrared OH-stretching absorption contours from pure and GeO<sub>2</sub>-doped fused silica corresponding to the fundamental and first three overtone regions have been examined and analyzed into Gaussian components. The fundamental spectral regio: has been shown to

consist of several OH-stretching fundamentals due to different silica environments, plus several nearby combinations involving silica vibrations. The fundamental component substructure has been found to carry over into each of the overtones resulting in a consistent pattern in good agreement with the requirements of anharmonicity and infrared activity. Critical assumptions concerning assignments of components in the fundamental region have been verified by comparisons with deuterated samples. The detailed overtone contours were obtained by using silica fibers, both pure and GeO<sub>2</sub>-doped, having lengths to 900 m. The major difference between the pure and GaO<sub>2</sub>-doped silica overtone contours involves a relative intensification and broadening of one of the Gaussian OH-stretching components, which is related to structural changes in the sinary glass network. The resultant OH-stretching overtone contours from GeO<sub>2</sub>-doped silica are considerably broader than from pure silica, primarily because of the broadening of this one component.

## 6. Acknowledgements

Special thanks are due to Dr. G. B. Wilmot, Research Department, Naval Surface Weapons Center, Dehigren, Virginia 22448, for making the Nicolet 7000 FTIR available for use and for generous assistance with it. The Raman instrument used in this work was purchased through a grant from the National Science Foundation, Chemical Thermodynamics Program, CHE-77-09888. The work was also funded in part by an ONR Contract at Howard University (Laser-Chemistry). We acknowledge the assistance of D. L. Bisbee for drawing some of the silica fibers, and C. A. Burrus for preparing the deuterated samples.

#### 7. Appendix

## A. Force Constants and Anharmonicity

The specific groupings of Gaussian-OH-stretching components of Table II, and the correlations of Fig. 3, involved considerations of anharmonicity. In Fig. 8, for example, a criterion was employed that all correlations must involve negative alopes, d(F/v)/dv, as

demanded by anharmonicity. Moreover, anharmonicity, mechanical and/or electrical, must be present for infrared and Raman overtone activity to occur at all. Thus, an infrared component in the fundamental OH-stretching spectrum at 3690 cm<sup>-1</sup> may not be correlated with an overtone  $\bar{r}/2$  position of 3690 cm<sup>-1</sup>, because overtone activity would be forbidden. Instead the 3690 cm<sup>-1</sup>, fundamental is correctly correlated with an overtone  $\bar{r}/2$  position of 3630 cm<sup>-1</sup>, Table II. Additional evidence for the correlations of Fig. 8 and the groupings of Table II comes from more detailed aspects of anharmonicity, Table III.

The fundamental infrared OH-stretching peak occurs near 3665 cm<sup>-1</sup>, and the fundamental Raman peak near 3690 cm<sup>-1</sup>. (2) From these values it was decided, Table III, that the first, second, and third overtone peaks correlate with the fundamental Raman peak rather than with the fundamental infrared peak. A factor in this decision involved the first difference,  $\Delta_1$ , between successive  $\overline{\nu}/\nu$  values. Also peak positions are more accurate than component positions.

Consider that the fundamental and overtone frequencies are given by  $\bar{r} = av - bv^2$ , or  $\bar{r}/v = a - bv$ . This means that first differences in  $\bar{r}/v$  values between neighboring vibrational levels are constant and equal to (-b). From Table III, it is evident that first differences  $\Delta_1$  are much more constant for row 2 where the fundamental Raman peak value is compared, than for row 1, where the fundamental infrared peak is compared. This indicates that the fundamental infrared peak is anomalous, i.e., that the infrared intensity at 3690 cm<sup>-1</sup> is unexpectedly weak, and it attests to the validity of the Raman and overtone comparisons, viz., that the 3690 cm<sup>-1</sup> component should be compared with the first, second, and third overtone components at 3630, 3665, and 3480 cm<sup>-1</sup>, resp., Table II.

The second differences  $\Delta_2$  of Table III suggest that a cubic rather than a quadratic equation is  $\frac{1}{2}$  is involved,  $\frac{1}{2}$  is  $\frac{1}{2}$  is involved,  $\frac{1}{2}$  is  $\frac{1}{2}$  involved. Fig. 7/ $v = a - bv + cv^2$ , because they are constant, (+2c, or -10 cm<sup>-1</sup>). In regard to constancy of  $\Delta_2$ , the peak data of Table III involving the Raman comparison are plotted in Fig. 8, along with component 1 values, which refer essentially to peak

values. Both plots indicate constant curvature,  $d^2(\overline{\nu}/\nu)/d\nu^2 = 2c = \Delta_2$ , as do the plots for components 2 and 3.

The least squares equations for component A (despite the fact that it is a combination), and for components 1-3, as well as for the peak values, Table III, are as follows:

(A) 
$$\overline{\nu}/v = 4012 \pm 56 - (179.5 \pm 51.1)v + (12.5 \pm 10.1)v^2$$
,

(1) 
$$\vec{p}/v = 3734 \pm 9 - (38.3 \pm 8.5)v + (-6.3 \pm 1.7)v^2$$
,

(2) 
$$i/v = 3692 \pm 6 - (15.5 \pm 5.7)v + (-12.5 \pm 1.1)v^2$$
,

(3) 
$$\overline{v}/v = 3624 \pm 45 - (-1.9 \pm 41.5)v + (-16.8 \pm 8.2)v^2$$
,

and (peai.)  $\overline{v}/v = 3740 \pm 1.7 \times 10^{-4} - (45.0 \pm 1.6 \times 10^{-4})v + (-5.0 \pm 3.1 \times 10^{-5})v^2$ .

The positive curvature for component A,  $\frac{d^2(\overline{\nu}/v)/dv^2}{2} = +12.5 \pm 10.1$ , compared to the negative curvature value of  $-(6.3\pm1.7)$ ,  $-(12.5\pm1.1)$ .  $-(16.8\pm8.2)$ , and  $-(5.0\pm3.1\times10^{-5})$ , respectively, for components 1-3 and the peak agree with the differing assignments, namely combinations versus overtones, Table I. Further, the b values must be positive, but the c values can be either positive or negative. All b values are positive, except for component 3 which yields  $b = (-1.9\pm41.5)$ . This b value is uncertain because of errors in component 3 peak frequency, and thus the negative sign is probably not significant.

The coefficients in the cubic equations  $\bar{r} = av - bv^2 + cv^3$  are related to fundamental constants, in cm<sup>-1</sup>, as follows:

$$a = \omega_0$$
,  $b = \omega_0 x_0$ ,  $c = \omega_0 y_0$ , and  $\omega_a = a + b + 3/4c$ . (19)

The force constant  $k_e^1 = 4\pi \mu c^3 \omega_e^2$  represents the curvature of the potential,  $d^2V/dr^2$ , at the equilibrium position,  $r_e$ . Values or  $\omega_e$  and  $k_e$  corresponding to the peak and component frequencies, 1-3, are as follows: (peak),  $\omega_e = 3781 \text{ cm}^{-1}$ ,  $k_e = 7.99 \times 10^5 \text{ dyn-cm}^{-1}$ ; (1)  $\omega_e = 10^{-1}$ 

3768 cm<sup>-1</sup>,  $k_e = 7.93 \times 10^5 \text{ dyn-cm}^{-1}$ ; (2)  $\omega_e = 3698 \text{ cm}^{-1}$ ,  $k_e = 7.64 \times 10^5 \text{ dyn-cm}^{-1}$ ; and (3)  $\omega_e = 3617 \text{ cm}^{-1}$ ,  $k_e = 7.31 \times 10^5 \text{ dyn-cm}^{-1}$ .

# B. Justification for the Use of Gaussian Components

Because Gaussian components were employed extensively for fundamental and overtone OH-stretching contours in this work, it is desirable to describe various consideration leading to their use. In fused silica, OH oscillators are thought to exhibit several preferred structures, e.g., free or gas-like OH groups (dangling OH groups), strongly bent and thus weak O-H-O hydrogen bonds, and strong or more linear hydrogen bonds. These preferred local structures cause a clustering of the OH frequencies about certains values, namely, the component centers.

The decoupled OH oscillators also sense structural distortions, which are both angular and extensional, and this effect leads to a large broadening about the component centers. Also, because fused silica is amorphous, the structural distortions are essentially random, and hence the component shape is Gaussian. No large Lorentzian character is obvious experimentally, although the Gaussian component shape could be envisioned as the envelope of a very great number of sharp overlapping Lorentzians whose wings are lost in the noise level near the base of the OH-stretching contour.

With regard to preferred local structures, it is useful to give an example which refers to the fundamental OH-stretching component at 3690 cm<sup>-1</sup>. The 3690 cm<sup>-1</sup> component occurs at a frequency only 60 cm<sup>-1</sup> below the zero-density vibrational extrapolation for H<sub>2</sub>O gas at 400°C. This indicates that the OH oscillators involved are nearly free or gas-like. A reasonable explanation for this high OH-stretching frequency in fused silica is that adjacent silanol groups are thought to be present, Si-OH HO-Si, 60 and if one OH group engages in a moderately strong and thus nearly linear hydrogen bond, O—H—O, the adjacent OH group injust be nearly free or dangling, because of the requirement that the Si—O—H angle is much less than 180°. (20) The situation is shown schematically by

Finally, Gaussian decomposition of Raman contours from pure fused silica in the region between 0 and 1100 cm. 1 has recently been very successful. (17) Accurate contour fits were obtained using only those Gaussian components whose centers correspond to experimentally observed features, such as peaks and well-characterized shoulders, that is, no extra components were employed.
